storage and circadian rhythms. Memory and learning have been studied in squirrels that cache their food, sometimes not returning until the next year. Singing mice provide a new model for studying speech and learning. Studies of wild rodents will undoubtedly give us a window into the genetics underlying phenotypic variation, further promoted by genome sequencing projects that extend beyond the usual model species (see www.genome.gov).

All of this diversity can be traced back to the first fossil rodents (Ischyromyoidae) from the late Paleocene of Asia. These primitive rodents, although donning a beaver-like skull, had the teeth and feet of a squirrel, and skeletal features suggestive of an arboreal lifestyle. And from so squirrely a beginning evolved endless rodential forms most beautiful — species as distinct as ungulate-like capybaras, raccoon-like viscachas, rabbit-like springhares, and otter-like muskrats. Rodents are an evolutionary success story — they were here long before us and these opportunistic survivors will certainly be here long after we are gone.

Perceptual processing is facilitated by ascribing meaning to novel stimuli
Gary Lupyan and Michael J. Spivey
Can the interpretation of a visual stimulus (normally conceived as a late visual process) influence the recognition of that same stimulus (normally conceived as an early visual process)? Access of meaning from vision can be extremely rapid [1-3]. If the visual processing of meaningful stimuli is supported by top-down feedback from conceptual representations [4,5], then meaningful stimuli may be processed more efficiently than meaningless stimuli. A difficulty with testing this prediction is that meaningfulness is often confounded with familiarity. It is well established that familiar stimuli are easier to process than unfamiliar stimuli [6]. In visual search tasks, finding a target among unfamiliar non-targets (such as $\text{Ns}$) is much more effortful than searching among familiar non-targets (such as $\text{N}$s) [7]. However, poor performance on unfamiliar stimuli may be due, not only to inexperience with them, but also to a failure to represent them as members of meaningful categories. If so, then ascribing meaning to otherwise unfamiliar stimuli should facilitate perceptual processing. We report here data from experiments using a visual search task which show that, when perceptually novel stimuli are treated as members of a known category, they are processed more efficiently. These results are simulated by a model implementing top-down feedback from category representations to visual features.

Participants ($N = 62$, ages 18–22) searched for the perceptually novel symbols $\text{N}$ and $\text{N}$, These symbols are 90° rotations of the numerals 5 and 2 rendered in a ‘digital’ font. This simple rotation reduces search efficiency by a factor of two [8], while preserving the low-level visual properties of the familiar upright numerals. To investigate whether differences in processing efficiency hinge on differences in
meaningfulness, participants were randomly assigned to one of two groups. Participants in the number group were instructed to think of the items as rotated 2s and 5s; participants in the symbol group were not. This paradigm allowed us to manipulate meaningfulness while keeping perceptual novelty constant.

Participants completed two search phases in counterbalanced order (240 total trials) searching for a among 1’s and vice versa (Figure 1A). On each trial, participants were asked to give a target-present or target-absent response while maintaining central fixation. After the experiment, participants were given a questionnaire asking whether they thought of (or mentally labeled) the stimuli as any kind of alphanumeric characters. The responses yielded three subgroups in the symbol group: those who spontaneously used their own labels for the stimuli consistently (N = 14), or inconsistently (N = 11), or not at all (N = 16). The number group yielded two subgroups: those who reported consistently thinking of the stimuli as rotated 2s and 5s, as instructed (N = 16), and those who did not label the stimuli despite the instructions (N = 5).

Analysis of the randomly assigned symbol and number groups revealed that participants in the symbol group had significantly slower reaction times than those assigned to the number group, target-present trials (Figure 1B). Moreover, participants’ reports of whether they conceived of the shapes as familiar characters predicted performance. Participants who were assigned to the number condition, or who spontaneously and consistently ascribed meaning to the stimuli, had significantly faster reaction times (M = 1.115 ms versus M = 1.431 ms), and searched more efficiently (47 ms per item versus 66 ms per item) than participants who treated the stimuli as meaningless. (For additional analyses, including error data, see the Supplemental data available on-line.)

To outline a possible mechanism for the neural components involved in this perceptual facilitation induced by stimulus meaningfulness, a localist attractor network that has successfully simulated reaction times during search [9] was modified to include an additional ‘category label’ component (Figure 1C). When activated, the category label provides top-down feedback to features associated with the target category. Each display was represented by seven feature vectors (each having as many nodes as stimuli in the display) that normalize their activation patterns to sum to 1.0, and then compute a weighted average at the search vector. During search for a among 1’s, the five thick connections in Figure 1C (features that are associated with the target) indicate stronger attentional weights, and the two thin connections (features uniquely associated with the non-targets) indicate weaker attentional weights. The search vector then sends feedback to the feature vectors by multiplying itself by the input that just traveled up from that feature vector. The feature vectors accumulate that feedback, and then renormalize to begin a new time cycle.

Without the top-down feedback from the category layer, the network produces a search slope of 60 ms per item. When the label layer is allowed to modulate the activity of the feature vectors with which it is associated (red lines in Figure 1C), the search efficiency is improved to 41 ms/item (Figure 1D).

Thus, as the label vector gradually becomes more confident that the target is present, its feedback subtly biases the feature vectors toward the target node (see Supplemental data for code).

Considering novel stimuli as instances of familiar categories significantly improved mean search times, search efficiency, and reduced false alarms (Figure S3 in the Supplemental data). Thus, ascribing meaning to perceptually unfamiliar stimuli improved visual processing. This facilitation can be modeled by a simple attractor network in which top-down feedback from category labels recurrently sharpens the distributions of activation within the feature vectors. The present findings are compatible with a range of theoretical accounts of reentrant visual processes [5,10,11]. Although the neural locus of the reported effect remains unspecified, a candidate lies in the corticocortical projections between the orbitofrontal (OFC) and inferotemporal (IT) cortex, with OFC providing prediction signals to IT [12]; this feedback is predicted to be more robust for meaningful objects.
Our findings demonstrate a possible behavioral outcome of a visual system with massive retrograde connections between category-sensitive and more primary visual areas [5,12] and suggest a reassessment of theories that eschew top-down conceptual influences on visual selection [13,14]. The present results make it clear that visual perception depends not only on what something looks like, but also on what it means.

Curious effect with reversed brain stimulation has rapidly become a popular method for treating patients with Parkinson’s disease [1], and is now widely recognised as one of the most effective long-term treatments. So far, the neural mechanisms underlying its effectiveness have been elusive. However, measuring saccadic latency — the time taken to look at a sudden visual stimulus — seems a promising approach. Latency varies randomly from trial to trial, and analysis of the resultant statistical distributions

Figure 1. Saccadic latency distributions.
Above: in the LATER model, a decision signal rises linearly from its initial value of $S_0$ at a rate $r$ until it reaches a threshold level $S_T$ at which point a response is initiated. Because $r$ varies randomly (following a normal distribution) on different trials, the time to reach threshold, and thus the latency, also varies randomly. Consequently, if reciprocal saccadic latencies are plotted as a cumulative histogram, using a probit ordinate, a straight line will be obtained (right).
